

Authors' Reply

Manuscript: TEVC-00054-2015.R1

Dear Editor,

We are grateful to Editors and referees for their insightful and very valuable comments and suggestions on the previous version of the paper. We have substantially revised the manuscript to adequately address these comments and suggestions. Below is a list of point-by-point statements about how we have responded to reviewers' comments. Major changes have been highlighted in blue in the revised manuscript.

Response to Associate Editor

The revised paper included an algorithmic extension and results on constrained problems, which is nice.

The second reviewer has raised some important issues, which authors must address. There are nice results in the paper, comparable to earlier studies such as NSGA-III, but the algorithm looks complex. So, authors need to make the following points clear in their final revision:

Response:

Many thanks for your encouraging comments on the previous version of our paper. We have made every effort to revise the paper to answer the questions raised by reviewer #2 and the comments by the AE.

1. In which major fundamental way, RVEA is different from existing decomposition based EMO algorithms for solving many-objective problems? Please ignore minor changes and different geometric ways to compute distances and angles.

In the abstract and in the body, authors claim that RVEA is a very different algorithm. This needs to be justified well in the next version or the claims need to be toned down and be made in tune with existing methods. While addressing the above, indicate how and why the differences produce better results.

Response:

Thanks for pointing out this issue, which has also been raised by Reviewer# 2. We have tried to clarify this in the previous version, which was unfortunately not successful, mainly due to the unclarified relationship between the proposed RVEA and the 'decomposition' based approaches in the literature.

Currently, there is no formal definition for 'decomposition' based approaches. We had the impression that decomposition based approaches are meant for aggregation based approaches and that is why we tried to stress the difference between RVEA and aggregation based approaches in the previous version of the paper. To clarify the definition of decomposition based approaches, we had some discussions with relevant experts, and now we understand that in general, decomposition based approaches may include any MOEAs that divide an MOP into a number of subtasks, each of them being either a single or multi-objective optimization sub-problem, and then solve them in a collaborative manner. A typical

example of such decomposition based algorithms is the MOEA/D-M2M, where decomposition is realized by dividing the entire Pareto front into a number of segments, each segment being a multi-objective sub-problem.

We fully agree that the framework level of the proposed RVEA falls into the above general definition of decomposition based algorithms such as MOEA/D-M2M, partly because the reference vectors are generated in a similar way to that in MOEA/D-M2M. Nevertheless, our original motivation was to use the reference vectors as a means to articulate user preferences, which can also be partly seen in our results presented in Section V, as well as those reported in our previous papers [53][54].

To summarize, the framework of the proposed RVEA can be categorized into a decomposition based approach when the reference vectors are generated without any specific user preferences, although our original motivation was to use the reference vectors to elucidate preferences. We have clarified this in the revised manuscript. In the following, we list the main differences between RVEA and existing decomposition based approaches:

- (1) The motivation of using reference vectors is not to “divide-and-conquer” the entire Pareto front. Our motivation was to use the reference vectors to select preferred solutions, which is demonstrated in our results presented in Section V, as well as those in our previous papers [53][54]. Note however, when the preferences are generated to cover the whole objective space, i.e., there is no specific preference, RVEA becomes a general decomposition based approach.
- (2) There is no “neighborhood control” in RVEA, which is commonly seen in existing decomposition based approaches. In existing approaches, the reproduction process is normally carried out in the neighborhood. In RVEA, the reproduction procedure is carried out globally in the whole population, exactly like many traditional evolutionary algorithms such as NSGA-II.
- (3) In RVEA, the selection criterion is based on a novel scalarization approach, termed APD, which is specifically designed for many-objective optimization. Note that existing scalarization approaches such as PBI and TCH were designed for multiobjective optimization and will become less efficient for balancing convergence and diversity when the number of objectives increases.

In view of the relationship between RVEA and the existing decomposition based approaches, we have toned down our statements in the Abstract, Introduction and the main body of the revised paper, as suggested by the AE.

2. RVEA seems to require a number of parameters -- α and t_{max} (eqn 9) and fr in Algorithm 3. How does one set these parameters? If another parameter-less EMO can produce similar results on most problems, why someone would be interested in RVEA which may require tuning of parameters?

Response:

Thanks for your comments. We agree that some existing MOEAs for many-objective optimization, such as NSGA-III, do not have any parameters to be fine-tuned, which is a clear advantage. On the other hand, although RVEA has two parameters, our empirical results indicate that the performance of RVEA is relatively insensitive to the setting of the parameters on different problems. As presented in Section IV-C, “ $\alpha = 2$ ” and “ $fr = 0.1$ ” have been used for all benchmark problems studied in this work, including the DTLZ problems, WFG problems, scaled DTLZ problems, and the constrained DTLZ problems. Detailed results of parameter sensitivity analysis are presented in Appendix III, which show that RVEA is insensitive to the settings of these two parameters.

Compared to the state-of-the-art parameter-less MOEAs, in particular NSGA-III (most other state-of-the-art MOEAs do have parameters too), the overall performance of RVEA on different problems studied in this work is the most robust. Furthermore, RVEA has been shown to be very effective in preference articulation in many-objective optimization, as presented in Section V.

Response to Reviewer #2

Although this paper has been improved to some extent, some major issues have not been well addressed. My major concerns are:

Response:

Many thanks for your very detailed and insightful comments, which have helped us to clarify the relationship between RVEA and existing decomposition based MOEAs.

1. Introduction

The authors classified all the multiobjective approaches into three categories: convergence enhancement, diversity management, as well as both of them. This classification is questionable. Actually, an efficient multiobjective evolutionary algorithm has to consider two aspects: convergence and diversity. If only one of them is considered, it will not work. In fact, all multiobjective algorithms mentioned in this paper consider both aspects simultaneously.

Response:

Thanks for your comment. We agree that diversity maintenance is needed in all MOEAs. In the revised manuscript, similar to the categorization described in [29] and [38], we classify existing approaches into (1) approaches for convergence enhancement; (2) decomposition based approaches; (3) performance indicator based approaches. Corresponding revisions made in Section I are highlighted.

2. Background

The description of this part is questionable too. Actually, ref vectors/weight vectors/direction vectors are the same thing used in decomposition based algorithms. No matter which term is used, one or multiple scalarizing functions are defined explicitly or implicitly. Ref vector based MOEAs including your proposed algorithm are decomposition based algorithms.

Response:

Many thanks for your comments, which has helped us to clarify the relationship between RVEA and decomposition based approaches. While we agree that weight vectors, reference points as well as reference vectors have all been used in decomposition based approaches (according to the more general definition as discussed above in our reply to AE's comments), we would like to note that they all were originally designated as means for preference articulation. In case there is no specific user preference, preference based approaches using weight vectors, reference points and reference vectors largely resemble those decomposition based approaches that aim to decompose the original MOO into a number of sub-problems,. However, they clearly distinguish when the weight vectors, reference points and reference vectors are used to elucidate user preferences, instead of finding a representative

subset of the entire Pareto front / surface. We would also like to note that finding a representative subset of the whole Pareto front / surface using a limited number of solutions is no longer practical for many-objective optimization. It is also interesting to note that the perpendicular distance to the weight vectors or reference vectors can be seen as a measure for maintaining diversity in decomposition based approaches, which, however, becomes a degree of satisfaction of predefined preferences in preference based approaches.

Nevertheless, we agree that RVEA is closely related to decomposition based approaches due to the following two reasons. First, RVEA uses reference vectors, which are generated in a similar way to MOEA/D-M2M when no specific preferences are available. Second, the selection criterion is a dynamically weighted aggregation of the distance to the origin of the reference vectors and the angle of the solution from the reference vectors.

The main differences between RVEA and existing decomposition based approaches have been highlighted in our response to the first comment of the AE.

We have accordingly revised Section II to discuss the relationship between the reference based MOEAs and decomposition based MOEAs.

3. RVEA

The algorithm's description is quite obscure. you should distinguish your contributions in algorithmic framework level and aggregation function level and explain your contribution in a clear and direct manner.

Response:

We apologize that RVEA was not clearly presented. To address this concern, we have stressed the similarity in algorithm framework between RVEA and MOEA/D-M2M in the revised work. In addition, we have added some discussions about the proposed selection criterion, i.e., the angle penalized distance. We hope the above changes would help the readers more easily understand our algorithm

a. In algorithmic level, your algorithm is an implementation or variant of MOEA/D-M2M.

RVEA is MOEA/D-M2M [51] in which $S=1$ and selection in line 7 in [51] is replaced by your proposed APD function. Please carefully read [51], MOEA/D-M2M is a generic framework. As pointed out in [51], any other selection can be used to replace line 7. The only tiny difference between RVEA and original MOEA/D-M2M is that you didn't consider the case of empty subpopulation.

In MOEA/D, a key issue is how each subproblem (also called subproblem agent) selects its solution or solutions. Each subproblem can be multiobjective or single obj. In nutshell, RVEA is just a MOEA/D in which each subproblem agent chooses one single solution from P_t . This selected solution should have the best APD value among all the solutions in a subregion defined by ref vectors as done in MOEA/D-M2M. Much work has been done on selection in MOEA/D framework. The following are several related papers on this topic.

iv): Y. Yuan, H. Xu, B. Wang, B. Zhang and X. Yao, Balancing Convergence and Diversity in Decomposition-Based Many-Objective Optimizers, *IEEE Transactions on Evolutionary Computation*, 2015.

Response:

Many thanks for your very detailed comments and the references. We fully agree that the objective space partition strategy proposed in MOEA/D-M2M offers a very efficient way for decomposing large problems, as also confirmed in some recent work [36] [37] [38]. The reasons why we did not present RVEA as a variant of MOEA/D-M2M in the previous version are as follows:

- (1) In RVEA, the motivation of objective space partition is not to decompose the original problems into a number of sub-problems, which we believe is less practical for many-objective optimization problems, as it is very unlikely to perform such approximation with a limited number of solutions. Instead, they are used to articulate preferences, as shown in Section V and [53][54]. Nevertheless, we fully agree that when the reference vectors in RVEA are generated in a similar way to that in MOEA/D-M2M, they do look very similar at the algorithmic level and RVEA can be seen as a decomposition based approach.
- (2) There are substantial differences between MOEA/D-M2M and RVEA at the reproduction and selection levels. In MOEA/D-M2M, new solutions are generated inside each subpopulation, while in RVEA, the new solutions are generated globally in the entire population (as there is no “subpopulation” maintained). In other words, the reproduction procedure in RVEA is different from the one in MOEA/D-M2M. So is the selection criterion.

We have now added some statements to clarify the relationship between MOEA/D-M2M and RVEA at the beginning of Section III-C. We have also discussed and included the references you pointed to our attention.

b. Aggregation function level: You use APD to define a single objective subproblem in MOEA/D. PBI is $d1 + \theta \cdot d_2$, and APD is $\sqrt{d1^2 + d2^2} \cdot (1 + a \cdot \text{angle})$. The main idea of these two methods are the same. In APD, the parameter ‘a’ is dynamically changed as the search processes. In fact, the parameter ‘theta’ in PBI can be tuned in a similar way. The current version has done some experiments to compare PBI and APD, you should give more solid arguments why APD is better than PBI. The setting of the parameter ‘theta’ in PBI used in this paper is the same as that in the original MOEA/D. This might not be a good choice since the original MOEA/D only considers the MOPs with two or three objectives.

Response:

Thanks for pointing this out. Yes, we agree that APD and PBI share a large degree of similarity in particular from the formulation point of view. However, the physical meanings are different. The main differences between PBI and APD are summarized below, which are also included in Section III-C-3.

(1) The diversity criterion / preference measure is based on difference in angle in RVEA, while it is the distance to the weight vector in PBI. The use of difference in angles has certain advantages over the distance for the following two reasons. Firstly, no matter what the exact distance a candidate solution is from the ideal point, the angle between the candidate solution and a reference vector is constant. Secondly, angles can be more easily normalized into the same range, e.g., $[0, 1]$.

(2) The penalty term, $P(\theta_{t,i,j})$ in APD is tailored for many-objective optimization, which is adaptive to the search process as well as the number of objectives, while the penalty item θ in PBI is a fixed parameter, which was originally designed for multi-objective optimization.

Thanks for your remarks on the setting of θ in PBI. The settings of θ used in this work is set as recommended in [36] and [38], where the same setting has been used in many-objective optimization. We are also aware that such a setting of θ may not be best suited for many-objective optimization, and similar adaptive mechanism to that in APD may improve the performance of PBI as well. This is, however, beyond the scope of this study.

4. Some statements/ arguments are not solid or even wrong. The following are several examples:

i) *“An extension of NSGA-II, known as NSGA-III, has been proposed [27] by introducing a niching strategy based on a set of predefined reference points to enhance the population diversity on the top of Pareto dominance.” (page 2, left column) Similar to NSGA-II, NSGA-III also uses non-dominated sorting to rank individuals in the population. In the case of many objective optimization, such a fitness assignment will lose the selection pressure towards the Pareto front. The use of multiple predefined reference points (i.e., multiple single objective subproblems) in NSGA-III is a vital strategy to ensure the convergence of population instead of the population diversity.*

Response:

Many thanks for pointing this out and sorry for the confusing remarks. We fully agree that the predefined reference set in NSGA-III essentially contributes to convergence, although they appear to have contributed to diversity maintenance.

We understand that reference points in NSGA-III de facto decompose the original MOO problem into sub-problems (however, we feel that the sub-problems remain to be multiobjective problems as dominance comparison has been used), in particular when the reference points are generated to cover the whole Pareto front. Meanwhile, they can also be understood as a bias towards the preferred solutions, which helps distinguish some non-dominated solutions from others and eventually speed up the convergence. We have revised the statements accordingly.

ii) *“For example, in the MOEA/D-M2M[51], Liu et al. have proposed to partition the objective space using some direction vectors, and the segment of the Pareto front in each subspace is approximated independently.” (page 3, right column) In MOEA/D-M2M, the segment of the Pareto front in each subspace is approximated in a collaborative manner. After producing a number of offspring solutions for each subspace, then the union of these offspring solutions and the population is portioned into K subspaces again. That is, the solutions produced from one subspace could be allocated to another subspace. In this sense, approximating the segments of subspaces are not independent.*

Response:

We appreciate your insightful comments. We meant that the selection is done separately and agree that ‘independently’ is too strong. We have now removed the statement in the revised manuscript.

iii) *“It can be seen from the above discussions that although both decomposition based MOEAs and reference based MOEAs employs a set of vectors, their essential function are quite different.” (page 3, right column)*

As mentioned above, reference based MOEAs are also decomposition based MOEAs since they use scalarizing functions in selection.

Response:

Many thanks for your comments. As we mentioned above, reference based approaches and decomposition based approaches are very similar when the weight vectors / reference vectors are generated uniformly with an aim to achieve representative solutions of the entire Pareto front. This is achievable in multiobjective optimization, however, less practical for many-objective optimization. We also indicated that the motivations of reference based approaches and decomposition based approaches will substantially differ if the weight vectors or reference vectors are specifically generated according to user preferences instead of evenly distributed. We have clarified these in the revised manuscript.

iv) *“Therefore, instead of normalizing the objectives, we propose to adapt the reference vectors according to the ranges of the objective values in the following manner: ...”*

The authors proposed a so-called new method to deal with the objectives with different scales. The method is equivalent to objective normalization. It is not difficult to prove it. The reply from the authors about the failure of objective normalization in RVEA doesn't convince me.

Response:

Many thanks for your comment. We agree that mathematically, objective normalization may be equivalent to reference vector adaption. However, technically, they are different. In our early study, we tried to adopt different objective normalization strategies (including the one for NSGA-III), but unfortunately, it turns out that objective normalization will cause a convergence problem for the proposed RVEA. Therefore, instead of normalizing the objectives, we try to adapt the reference vectors to the different scales of the objectives.

In the revised manuscript, we have added some more detailed discussions on why objective normalization does not work in RVEA, which can be found in Section III-D, on Page 6.

In conclusion, the current version is not satisfactory. The author should use Occam's razor to polish their paper and make it clear what's their own contribution, try not to use new terms to name old ideas. The algorithm framework is not new. The APD may be interesting. However, solid investigation should be done on it. Wrong statements also need to be corrected. Every statement/argument should be supported by solid arguments.

Response:

We appreciate the time and effort for providing detailed reviews of our paper, which has also helped us to better understand various issues in multi- and many-objective optimization. We apologize for the unclearness in presentation of RVEA in the previous manuscript. Based on your comments, we have made substantial revisions to clarify the relationship between RVEA and existing decomposition

based approaches and new contributions of the paper. We understand that many-objective optimization is a new area where many issues remain to be clarified and better understood.

There are still some typos. The authors should also do the proofreading very carefully. For example, Page 3, right column, line 51, 'discussios'--> 'discussions'

Page 7, left column, line 26, 'Fig. 3(a)'--> 'Fig.3(b)'

Page 7, right column, line 28, 'Appendix ??'. The appendix number is missing.

Response:

Many thanks for pointing out the typos. We have corrected the typos and carefully proof-read the paper.

A Reference Vector Guided Evolutionary Algorithm for Many-objective Optimization

Ran Cheng, Yaochu Jin, *Senior Member, IEEE*, Markus Olhofer and Bernhard Sendhoff, *Senior Member, IEEE*

Abstract—In evolutionary multi-objective optimization, maintaining a good balance between convergence and diversity is particularly crucial to the performance of the evolutionary algorithms. In addition, it becomes increasingly important to incorporate user preferences because it will be less likely to achieve a representative subset of the Pareto optimal solutions using a limited population size as the number of objectives increases. This paper proposes a reference vector guided evolutionary algorithm for many-objective optimization. The reference vectors can not only be used to decompose the original multi-objective optimization problem into a number of single-objective sub-problems, but also to elucidate user preferences to target a preferred subset of the whole Pareto front. In the proposed algorithm, a scalarization approach, termed angle penalized distance, is adopted to balance convergence and diversity of the solutions in the high-dimensional objective space. An adaptation strategy is proposed to dynamically adjust the distribution of the reference vectors according to the scales of the objective functions. Our experimental results on a variety of benchmark test problems show that the proposed algorithm is highly competitive in comparison with five state-of-the-art evolutionary algorithms for many-objective optimization. In addition, we show that reference vectors are effective and cost-efficient for preference articulation, which is particularly desirable for many-objective optimization. Furthermore, a reference vector regeneration strategy is proposed for handling irregular Pareto fronts. Finally, the proposed algorithm is extended for solving constrained many-objective optimization problems.

Index Terms—Evolutionary multiobjective optimization, reference vector, many-objective optimization, convergence, diversity, preference articulation, scalarization approach, decomposition

I. INTRODUCTION

MULTIOBJECTIVE optimization problems (MOPs), which involve more than one conflicting objective to be optimized simultaneously, can be briefly formulated as follows:

$$\begin{aligned} \min_{\mathbf{x}} \quad & \mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_M(\mathbf{x})) \\ \text{s.t.} \quad & \mathbf{x} \in X \end{aligned} \quad (1)$$

where $X \subseteq \mathbb{R}^n$ is the decision space with $\mathbf{x} = (x_1, x_2, \dots, x_n) \in X$ being the decision vector. Due to the conflicting nature of the objectives, usually, there does not exist one single solution that is able to optimize all the

objectives simultaneously. Instead, a set of optimal solutions representing the trade-offs between different objectives, termed Pareto optimal solutions, can be achieved. The Pareto optimal solutions are known as the Pareto front (PF) in the objective space and the Pareto set (PS) in the decision space, respectively.

Evolutionary algorithms (EAs), as a class of population based search heuristics, are able to obtain a set of solutions in a single run. Thanks to this attractive property, multiobjective evolutionary algorithms (MOEAs) have witnessed a boom of development over the past two decades [1]. MOEAs have been shown to perform well on a wide range of MOPs with two or three objectives; however, MOEAs have experienced substantial difficulties when they are adopted to tackle MOPs with more than three objectives [2]–[5], often referred to as the many-objective problems (MaOPs) nowadays. As a result, MaOPs have attracted increasing attention in evolutionary optimization [6].

One major reason behind the failure of most conventional MOEAs in solving MaOPs can be attributed to the loss of selection pressure, i.e., the pressure for the population to converge towards the PF, when dominance is adopted as a criterion for selecting individuals with a limited population size [7]. For example, the elitist non-dominated sorting genetic algorithm (NSGA-II) [8] and the strength Pareto evolutionary algorithm 2 (SPEA2) [9], both of which use dominance-based selection, will fail to work properly for MaOPs, since most candidate solutions generated in a population of a limited size are non-dominated, making the dominance based selection criterion hardly possible to distinguish the candidate solutions, even in a very early stage of the search.

Another important reason for the degraded performance of MOEAs on MaOPs is the difficulty in maintaining a good population diversity in a high-dimensional objective space. Generally speaking, since the PF of most continuous MOPs is piecewise continuous [10], [11], it is practically unlikely to approximate all Pareto optimal solutions. Instead, most MOEAs aim to find a set of evenly distributed representative solutions to approximate the PF. When the number of objectives is two or three, where the PF is typically a one-dimensional curve or two-dimensional surface, maintaining a good diversity of the solutions is relatively straightforward. As the dimension of the objective space increases, it becomes increasingly challenging to maintain a good population diversity, as the candidate solutions distribute very sparsely in the high-dimensional objective space, causing immense difficulties to the diversity management strategies widely used in MOEAs, e.g., the crowding distance base diversity method in NSGA-

II [12]–[14].

To enhance the performance of most traditional MOEAs in solving MaOPs, a number of approaches have been proposed [15], [16], which can be roughly divided into three categories.

The first category covers various approaches to convergence enhancement. Since the loss of convergence pressure in most traditional MOEAs is directly caused by the inability of the canonical dominance to distinguish solutions, the most intuitive idea for convergence enhancement is to modify the dominance relationship to increase the selection pressure towards the PF. Examples of modified dominance definitions include ϵ -dominance [17], [18], L -optimality [19], preference order ranking [20] and fuzzy dominance [21]. In [22], a grid dominance based metric is defined for solving MaOPs, termed grid-based evolutionary algorithm (GrEA), which eventually modifies the dominance criterion to accelerate the convergence in many-objective optimization. Another typical idea in this category is to combine the Pareto dominance based criterion with additional convergence-related metrics. For example, Köppen and Yoshida [23] propose to use some substitute distances to describe the degree to which a solution almost dominates another to improve the performance of NSGA-II. In [24], a binary ϵ -indicator based preference is combined with dominance to speed up convergence of NSGA-II for solving MaOPs. In [25], a shift-based density estimation strategy is proposed to penalize poorly converged solutions by assigning them a high density value in addition to dominance comparison. A recently proposed evolutionary algorithm, termed knee point driven evolutionary algorithm (KnEA) introduces a knee point based selection criterion to enhance convergence in many-objective optimization [26].

The second category is often known as the decomposition based approaches, which divide a complex MOP into a number of sub-problems and solve them in a collaborative manner [27], [28]. There are mainly two types of decomposition based approaches [29]. In the first type of decomposition based approaches, an MOP is decomposed into a group of single-objective problems (SOPs), including the weighted aggregation based approaches in early days [30], [31], and the more recent multiobjective evolutionary algorithm based on decomposition (MOEA/D), where more explicit collaboration strategies between the solutions of the sub-problems were introduced. Several variants of MOEA/D have been proposed for enhancing the selection strategy for each sub-problem to strike a better balance between convergence and diversity [29], [32]–[34].

In the second type of decomposition based approaches, an MOP is decomposed into a group of sub-MOPs. For instance, MOEA/D-M2M [28], [35] divides the whole PF into a group of segments, and each segment can be regarded as a sub-problem. Another MOEA that essentially falls under this category is NSGA-III [36], where a set of predefined, evenly distributed reference points to manage the diversity of the candidate solutions, eventually contribute to enhanced convergence of the algorithm. Although the second type of decomposition strategy has been reported very efficient in some recent works [37], [38], compared to the first type, its

development is still in the infancy.

The third category is known as the performance indicator based approaches, e.g., the indicator based evolutionary algorithm (IBEA) [39], the S-metric selection based evolutionary multi-objective algorithm (SMS-EMOA) [40], a dynamic neighborhood multi-objective evolutionary algorithm based on hypervolume indicator (DNMOEA/HI) [41], and the fast hypervolume based evolutionary algorithm (HypE) [42]. These approaches are not subject to the issues that dominance based MOEAs have for solving MaOPs. Unfortunately, the computational cost for the calculation of the performance becomes prohibitively expensive when the number of objectives is large [43].

There are also a few approaches that do not fall into any of the above three main categories. For example, some researchers propose to use interactive user preferences [44] or reference points [45] during the search while others suggest to solve MaOPs by using a reduced set of objectives [46], [47]. Another example is a recently proposed evolutionary many-objective optimization algorithm based on both dominance and decomposition (MOEA/DD) [38], the motivation of which is to exploit the merits offered by both dominance and decomposition based approaches. More recently, a two-archive algorithm for many-objective optimization (Two_Arch2) has been proposed based on indicator and dominance [48].

While most existing MOEAs focusing on convergence enhancement and diversity maintenance, it is noted that use of preferences will become particularly important for many-objective optimization, not only because the user may be interested in only part of Pareto optimal solutions, but also because it is less practical to achieve a representative subset of the whole PF using an evolutionary algorithm of a limited population size.

As already shown in [36], reference points can also be used to generate a subset of preferred Pareto optimal solutions, although NSGA-III can be seen as a decomposition based approach if the reference points are evenly distributed in the whole objective space. Motivated by ideas in decomposition based approaches and the aim to achieve the preferred part of the PF when the number of objectives is large, we propose a reference vector guided evolutionary algorithm (RVEA) for solving MaOPs. Compared with existing decomposition based approaches, the main new contributions of this work can be summarized as follows:

- (1) A scalarization approach, termed as the angle penalized distance (APD), is designed to dynamically balance convergence and diversity in many-objective optimization according to the number of objectives and the number of generations. In the proposed APD, the convergence criterion is measured by the distance between the candidate solutions and the ideal point¹, and the diversity criterion is measured by the acute angle between the candidate solutions and the reference vectors. Note that if the reference vectors are used to represent user preferences, this angle also indicates the degree of satisfaction of the

¹For a minimization problem, the ideal point is a vector that consists of the minimum value of each objective function.

user preferences.

- (2) An adaptive strategy is proposed to adjust the reference vectors to deal with objective functions that are not well normalized. The adaptive strategy adjusts the distribution of the reference vectors according to the ranges of different objective functions in order to ensure a uniform distribution of the candidate solutions in the objective space, even if the objective functions are not well normalized or the geometrical structure of a PF is highly asymmetric. This strategy is mainly for achieving an evenly distributed Pareto optimal subset.
- (3) It is shown that reference vectors can also provide an effective and computationally efficient approach to preference articulation. Such preference articulation is particularly valuable in many-objective optimization, where it is very unlikely to obtain a representative approximation of the whole PF [49]. By specifying a central vector and a radius, we propose a reference vector based preference articulation approach that is able to generate evenly distributed Pareto optimal solutions in a preferred region in the objective space.
- (4) To enhance the performance of the proposed RVEA on problems with irregular² Pareto fronts, a reference vector regeneration strategy is proposed. The basic idea is to use an additional reference vector set to perform exploration in the objective space so that the density of the solutions obtained by RVEA on problems with irregular Pareto fronts can be improved.
- (5) The proposed RVEA is further extended for solving constrained MaOPs.

The rest of this paper is organized as follows. Section II introduces some background knowledge. The details of the proposed RVEA are described in Section III. Section IV presents empirical results that compare the performance of RVEA with five state-of-the-art MOEAs for solving MaOPs. In addition, preference articulation using reference vectors is exemplified in Section V, a reference vector regeneration strategy for irregular Pareto fronts handling is presented in Section VI, and the extension of RVEA to handling constrained MaOPs is presented in Section VII. Finally, conclusions and future work are given in Section VIII.

II. BACKGROUND

In this section, we first present a brief review of decomposition based MOEAs. Then, an introduction to the reference vectors used in this work is given, including how to sample uniformly distributed reference vectors and how to measure the spacial relationship between two vectors.

A. Decomposition based MOEAs

In weight aggregation based decomposition approaches [31], [50], [51], a set of *weight vectors* are used to convert an MOP into a number of SOPs using a scalarization method. Among others, the weighted sum

approach, the weighted Tchebycheff approach [52] and the penalty-based boundary intersection (PBI) approach [50] are most widely used.

More recently, a set of weight vectors are used to divide an MOP into a number of sub-problems by partitioning the entire objective space into some subspaces, where each sub-problem remains an MOP. This type of decomposition strategy was first proposed by Liu *et al.* in [28], where a set of *direction vectors* are used to divide the whole PF into a number of segments, each segment being a multi-objective sub-problem. Such a decomposition strategy has attracted certain interests. For example, in NSGA-III [36], a set of *reference points* or *reference lines* are used for niche preservation to manage diversity in each subspace for many-objective optimization, which effectively enhances convergence by giving priority to solutions closer to the reference points. Most recently, an inverse model based MOEA (IM-MOEA) [37] has been suggested, where a set of *reference vectors* are used to partition the objective space into a number of subspaces and then inverse models that map objective vectors onto decision vectors are built inside each subspace for sampling new candidate solutions.

Since *weight vectors* are typically used to denote the importance of objectives in weighted aggregation, different terminologies have been coined in the second type of decomposition based approaches to refer to vectors that decompose the original objective space, including *direction vectors* [28], *reference lines* [36], and *reference vectors* [37]. In essence, these vectors play a similar role of partitioning the objective space into a number of subspaces. In this work, we adopt the term *reference vectors*.

When a set of evenly distributed reference vectors are generated for achieving representative solutions of the whole PF, the proposed RVEA can be considered as one of the second type of decomposition based approaches. However, if user preferences are available and a set of specific reference vectors are generated for achieving only a preferred section of the PF, RVEA can also be seen as a preference based approach. For example in [53], [54], a set of reference vectors have been used to achieve preferred subset of the Pareto-optimal solutions. Note however, that RVEA differs from most existing reference point based MOEAs [55]–[57] in that these algorithms use dominance and preference to search for preferred subset of the PF only.

B. Reference Vector

Without loss of generality, all the reference vectors used in this work are unit vectors inside the first quadrant with the origin being the initial point. Theoretically, such a unit vector can be easily generated via dividing an arbitrary vector by its norm. However, in practice, uniformly distributed unit reference vectors are required for a uniformly distributed coverage of the objective space. In order to generate uniformly distributed reference vectors, we adopt the approach introduced in [37]. Firstly, a set of uniformly distributed points on a unit hyperplane are generated using the canonical simplex-

²In this work, irregular Pareto fronts refer to disconnected and degenerate Pareto fronts.

Fig. 1. An illustration of how to generate the uniformly distributed reference vectors in a three-objective space. In this case, 10 uniformly distributed reference points are first generated on a hyperplane, and then they are mapped to a hypersphere to generate the 10 reference vectors.

lattice design method [58]:

$$\begin{cases} \mathbf{u}_i = (u_i^1, u_i^2, \dots, u_i^M), \\ u_i^j \in \{\frac{0}{H}, \frac{1}{H}, \dots, \frac{H}{H}\}, \sum_{j=1}^M u_i^j = 1, \end{cases} \quad (2)$$

where $i = 1, \dots, N$ with N being the number of uniformly distributed points, M is the objective number, and H is a positive integer for the simplex-lattice design. Then, the corresponding unit reference vectors \mathbf{v}_i can be obtained by the following transformation:

$$\mathbf{v}_i = \frac{\mathbf{u}_i}{\|\mathbf{u}_i\|}, \quad (3)$$

which maps the reference points from a hyperplane to a hypersphere, an example of which is shown in Fig. 1. According to the property of the simplex-lattice design, given H and M , a total number of $N = \binom{H+M-1}{M-1}$ uniformly distributed reference vectors can be generated.

Given two vectors \mathbf{v}_1 and \mathbf{v}_2 , the cosine value of the acute angle θ between the two vectors can be used to measure the spatial relationship between them, which is calculated as follows:

$$\cos \theta = \frac{\mathbf{v}_1 \cdot \mathbf{v}_2}{\|\mathbf{v}_1\| \|\mathbf{v}_2\|}, \quad (4)$$

where $\|\cdot\|$ calculates the norm, i.e., the length of the vector. As will be introduced in the following section, in the proposed RVEA, (4) can be used to measure the spacial relationship between an objective vector and a reference vector in the objective space. Since they have already been normalized as in (2) when generated, the reference vectors no longer need to be normalized again in calculating the cosine values.

III. THE PROPOSED RVEA

A. Elitism Strategy

The main framework of the proposed RVEA is listed in Algorithm 1, from which we can see that RVEA adopts an elitism strategy similar to that of NSGA-II [8], where the offspring population is generated using traditional genetic operations such as crossover and mutation, and then the offspring population is combined with the parent population

Algorithm 1 The main framework of the proposed RVEA.

- 1: **Input:** the maximal number of generations t_{max} , a set of unit reference vectors $V_0 = \{\mathbf{v}_{0,1}, \mathbf{v}_{0,2}, \dots, \mathbf{v}_{0,N}\}$;
- 2: **Output:** final population $P_{t_{max}}$;
- 3: /*Initialization*/
- 4: **Initialization:** create the initial population P_0 with N randomized individuals;
- 5: /*Main Loop*/
- 6: **while** $t < t_{max}$ **do**
- 7: $Q_t = \text{offspring-creation}(P_t)$;
- 8: $P_t = P_t \cup Q_t$;
- 9: $P_{t+1} = \text{reference-vector-guided-selection}(t, P_t, V_t)$;
- 10: $V_{t+1} = \text{reference-vector-adaptation}(t, P_{t+1}, V_t, V_0)$;
- 11: $t = t + 1$;
- 12: **end while**

to undergo an elitism selection. The main new contributions in the RVEA lie in the two other components, i.e., the reference vector guided selection and the reference vector adaptation. In addition, RVEA requires a set of predefined reference vectors as the input, which can either be uniformly generated using (2) and (3), or specified according to the user preferences, which will be introduced in Section V. In the following subsections, we will introduce the three main components in Algorithm 1, i.e., offspring creation, reference vector guided selection and reference vector adaptation.

B. Offspring Creation

In the proposed RVEA, the widely used genetic operators, i.e., the simulated binary crossover (SBX) [59] and the polynomial mutation [60] are employed to create the offspring population, as in many other MOEAs [22], [26], [27], [36], [42]. Here, we do not apply any explicit mating selection strategy to create the parents; instead, given N individuals in the current population P_t , a number of $\lfloor N/2 \rfloor$ pair of parents are randomly generated, i.e., each of the N individuals has an equal probability to participate in the reproduction procedure. This is made possible partly thanks to the reference vector guided selection strategy, which is able to effectively manage the convergence and diversity inside small subspaces of the objective space such that the individual inside each subspace can make an equal contribution to the population. Nevertheless, specific mating selection strategies can be helpful in solving problems having a multimodal landscape or a complex Pareto set [61].

C. Reference Vector Guided Selection

Similar to MOEA/D-M2M [28], [35], RVEA partitions the objective space into a number of subspaces using the reference vectors, and selection is performed separately inside each subspace. Specifically, the proposed reference vector guided selection strategy consists of four steps: objective value translation, population partition, angle penalized distance calculation and the elitism selection.

1) *Objective Value Translation*: According to the definition in Section II-B, the initial point of the reference vectors used in this work is always the coordinate origin. To be consistent with this definition, the objective values of the individuals in population P_t , denoted as $F_t = \{\mathbf{f}_{t,1}, \mathbf{f}_{t,2}, \dots, \mathbf{f}_{t,|P_t|}\}$, where t is the generation index, are translated³ into F'_t via the following transformation:

$$\mathbf{f}'_{t,i} = \mathbf{f}_{t,i} - \mathbf{z}_t^{\min}, \quad (5)$$

where $i = 1, \dots, |P_t|$, $\mathbf{f}_{t,i}$, $\mathbf{f}'_{t,i}$ are the objective vectors of individual i before and after the translation, respectively, and $\mathbf{z}_t^{\min} = (z_{t,1}^{\min}, z_{t,2}^{\min}, \dots, z_{t,m}^{\min})$ represents the minimal objective values calculated from F_t . The role of translation operation is twofold: (1) to guarantee that all the translated objective values are inside the first quadrant, where the extreme point of each objective function is on the corresponding coordinate axis, thus maximizing the coverage of the reference vectors; (2) to set the ideal point to be the origin of the coordinate system, which will simplify the formulations to be presented later on. Some empirical results showing the significance of the objective value translation can be found in Supplementary Materials I.

Fig. 2. An example showing how to associate an individual with a reference vector. In this example, \mathbf{f}' is a translated objective vector, \mathbf{v}_1 and \mathbf{v}_2 are two unit reference vectors. θ_1 and θ_2 are the angles between \mathbf{f}' and \mathbf{v}_1 , \mathbf{v}_2 , respectively. Since $\theta_2 < \theta_1$, the individual denoted by \mathbf{f}' is associated with reference vector \mathbf{v}_2 .

2) *Population Partition*: After the translation of the objective values, population P_t is partitioned into N subpopulations $\bar{P}_{t,1}, \bar{P}_{t,2}, \dots, \bar{P}_{t,N}$ by associating each individual with its closest reference vector, referring to Fig. 2, where N is the number of reference vectors. As introduced in Section II-B, the spacial relationship of two vectors is measured by the acute angle between them, i.e., the cosine value between an objective vector and a reference vector can be calculated as:

$$\cos \theta_{t,i,j} = \frac{\mathbf{f}'_{t,i} \cdot \mathbf{v}_{t,j}}{\|\mathbf{f}'_{t,i}\|}, \quad (6)$$

where $\theta_{t,i,j}$ represents the angle between objective vector $\mathbf{f}'_{t,i}$ and reference vector $\mathbf{v}_{t,j}$.

³In Euclidean geometry, a translation is a rigid motion that moves every point a constant distance in a specified direction.

In this way, an individual $I_{t,i}$ is allocated to a subpopulation $\bar{P}_{t,k}$ if and only if the angle between $\mathbf{f}'_{t,i}$ and $\mathbf{v}_{t,k}$ is minimal (i.e., the cosine value is maximal) among all the reference vectors:

$$\bar{P}_{t,k} = \{I_{t,i} | k = \operatorname{argmax}_{j \in \{1, \dots, N\}} \cos \theta_{t,i,j}\}, \quad (7)$$

where $I_{t,i}$ denotes the i -th individual in P_t , with $i = 1, \dots, |P_t|$.

Algorithm 2 The reference vector guided selection strategy in the proposed RVEA.

```

1: Input: generation index  $t$ , population  $P_t$ , unit reference
   vector set  $V_t = \{\mathbf{v}_{t,1}, \mathbf{v}_{t,2}, \dots, \mathbf{v}_{t,N}\}$ ;
2: Output: population  $P_{t+1}$  for next generation;
3: /*Objective Value Translation*/
4: Calculate the minimal objective values  $\mathbf{z}_t^{\min}$ ;
5: for  $i = 1$  to  $|P_t|$  do
6:    $\mathbf{f}'_{t,i} = \mathbf{f}_{t,i} - \mathbf{z}_t^{\min}$ ; //refer to (5)
7: end for
8: /*Population Partition*/
9: for  $i = 1$  to  $|P_t|$  do
10:   for  $j = 1$  to  $N$  do
11:      $\cos \theta_{t,i,j} = \frac{\mathbf{f}'_{t,i} \cdot \mathbf{v}_{t,j}}{\|\mathbf{f}'_{t,i}\|}$ ; //refer to (6)
12:   end for
13: end for
14: for  $i = 1$  to  $|P_t|$  do
15:    $k = \operatorname{argmax}_{j \in \{1, \dots, N\}} \cos \theta_{t,i,j}$ ;
16:    $\bar{P}_{t,k} = \bar{P}_{t,k} \cup \{I_{t,i}\}$ ; //refer to (7)
17: end for
18: /*Angle-Penalized Distance (APD) Calculation*/
19: for  $j = 1$  to  $N$  do
20:   for  $i = 1$  to  $|\bar{P}_{t,j}|$  do
21:      $d_{t,i,j} = (1 + P(\theta_{t,i,j})) \cdot \|\mathbf{f}'_{t,i}\|$ ; //refer to (8) (9) (10)
22:   end for
23: end for
24: /*Elitism Selection*/
25: for  $j = 1$  to  $N$  do
26:    $k = \operatorname{argmin}_{i \in \{1, \dots, |\bar{P}_{t,j}|\}} d_{t,i,j}$ ;
27:    $P_{t+1} = P_{t+1} \cup \{I_{t,k}\}$ ;
28: end for
    
```

3) *Angle-Penalized Distance (APD) Calculation*: Once the population P_t is partitioned into N subpopulations $\bar{P}_{t,1}, \bar{P}_{t,2}, \dots, \bar{P}_{t,N}$, one elitist can be selected from each subpopulation to create P_{t+1} for the next generation.

Since our motivation is to find the solution on each reference vector that is closest to the ideal point, the selection criterion consists of two sub-criteria, i.e., the convergence criterion and the diversity criterion, with respect to the reference vector that the candidate solutions are associated with.

Specifically, given a translated objective vector $\mathbf{f}'_{t,i}$ in subpopulation j , the convergence criterion can be naturally

represented by the distance from $\mathbf{f}'_{t,i}$ to the ideal point⁴, i.e., $\|\mathbf{f}'_{t,i}\|$; and the diversity criterion is represented by the acute angle between $\mathbf{f}'_{t,i}$ and $\mathbf{v}_{t,j}$, i.e., $\theta_{t,i,j}$, as the inverse function value of $\cos \theta_{t,i,j}$ calculated in (6). In order to balance between the convergence criterion $\|\mathbf{f}'_{t,i}\|$ and the diversity criterion $\theta_{t,i,j}$, a scalarization approach, i.e., the *angle-penalized distance (APD)* is proposed as follows:

$$d_{t,i,j} = (1 + P(\theta_{t,i,j})) \cdot \|\mathbf{f}'_{t,i}\|, \quad (8)$$

with $P(\theta_{t,i,j})$ being a penalty function related to $\theta_{t,i,j}$:

$$P(\theta_{t,i,j}) = M \cdot \left(\frac{t}{t_{max}}\right)^\alpha \cdot \frac{\theta_{t,i,j}}{\gamma_{\mathbf{v}_{t,j}}}, \quad (9)$$

and

$$\gamma_{\mathbf{v}_{t,j}} = \min_{i \in \{1, \dots, N\}, i \neq j} \langle \mathbf{v}_{t,i}, \mathbf{v}_{t,j} \rangle, \quad (10)$$

where M is the number of objectives, N is the number of reference vectors, t_{max} is the predefined maximal number of generations, $\gamma_{\mathbf{v}_{t,j}}$ is the smallest angle value between reference vector $\mathbf{v}_{t,j}$ and the other reference vectors in the current generation, and α is a user defined parameter controlling the rate of change of $P(\theta_{t,i,j})$. The detailed design of the penalty function $P(\theta_{t,i,j})$ in the APD calculation is based on the following empirical observations.

Firstly, in many-objective optimization, since the candidate solutions are sparsely distributed in the high-dimensional objective space, it is not the best to apply a constant pressure on convergence and diversity in the entire search process. Ideally, at the early stage of the search process, a high selection pressure on convergence is exerted to push the population towards the PF, while at the late search stage, once the population is close to the PF, population diversity can be emphasized in selection to generate well distributed candidate solutions. The penalty function, $P(\theta_{t,i,j})$, is exactly designed to meet these requirements. Specifically, at the early stage of the search process (i.e., $t \ll t_{max}$), $P(\theta_{t,i,j}) \approx 0$, and thus $d_{t,i,j} \approx \|\mathbf{f}'_{t,i}\|$ can be satisfied, which means that the value of $d_{t,i,j}$ is mainly determined by the convergence criterion $\|\mathbf{f}'_{t,i}\|$; while at the late stage of the search process, with the value of t approaching t_{max} , the influence of $P(\theta_{t,i,j})$ will be gradually accumulated to emphasize the importance of the diversity criterion $\theta_{t,i,j}$.

Angle $\gamma_{\mathbf{v}_{t,j}}$ is used to normalize the angles in the subspace specified by $\mathbf{v}_{t,j}$. This angle normalization process is particularly meaningful when the distribution of some reference vectors is either too dense (or too sparse), resulting in extremely small (or large) angles between the candidate solutions and the reference vectors. Compared to most existing objective normalization approaches, e.g., the one adopted in NSGA-III [36], the proposed angle normalization approach has two major differences: (1) normalizing the angles (instead of the objectives) will not change the actual positions of the candidate solutions, which is important convergence information for the

proposed RVEA; (2) angle normalization, which is independently carried out inside each subspace, does not influence the distribution of the candidate solutions in other subspaces.

In addition, since the sparsity of the distribution of the candidate solutions is directly related to the dimension of the objective space, i.e., the value of M , the penalty function $P(\theta_{t,i,j})$ is also related to M to adaptively adjust the range of the penalty function values.

According to the angle penalized distances calculated using (8) and (9), the individual in each subpopulation having the minimal distance is selected as the elitist to be passed to the population for the next generation. The pseudo code of the reference vector guided selection procedure is summarized in Algorithm 2.

It is worth noting that the formulation of the proposed APD shares some similarity to the penalty-based boundary intersection (PBI) [50], which is widely adopted in the decomposition based MOEAs. However, there are two major differences between APD and PBI:

- (1) In APD of the proposed RVEA, the angle between the reference vector and the solution vector is calculated for measuring diversity or the degree of satisfaction of the user preference, while in PBI, the distance of the solution to the weight vector is calculated, which is a sort of diversity measure. Calculation of the difference in angle has certain advantages over calculation of the distance for the following two reasons. First, no matter what the exact distance a candidate solution is from the ideal point, the angle between the candidate solution and a reference vector is constant. Second, angles can be more easily normalized into the same range, e.g., $[0, 1]$.
- (2) The penalty item $P(\theta_{t,i,j})$ in APD is tailored for many-objective optimization, which is adaptive to the search process as well as the number of objectives, while the penalty item θ in PBI is a fixed parameter, which was originally designed for multiobjective optimization.

Empirical results on comparing the proposed APD approach and the PBI approach can be found in Section IV-F.

D. Reference Vector Adaptation

Given a set of uniformly distributed unit reference vectors, the proposed RVEA is expected to obtain a set of uniformly distributed Pareto optimal solutions that are the intersection points between each reference vector and the PF, as shown in Fig. 3(a). However, this happens only if the function values of all objectives can be easily normalized into the same range, e.g., $[0, 1]$. Unfortunately, in practice, there may exist MaOPs where different objectives are scaled to different ranges, e.g., the WFG test problems [62] and the scaled DTLZ problems [36]. In this case, uniformly distributed reference vectors will not produce uniformly distributed solutions, as shown in Fig. 3(b).

One intuitive way to address the above issue is to carry out objective normalization dynamically as the search proceeds. Unfortunately, it turns out that objective normalization is not suited for the proposed RVEA, mainly due to the following reasons:

⁴As the objective values have been translated by subtracting the minimal value of each objective function in (5), the ideal point is always the coordinate origin. Therefore, the distance from a translated objective vector to the ideal point equals the norm (length) of the translated objective vector.

(a) Pareto optimal solutions specified by 10 uniformly distributed reference vectors on a PF with objectives normalized to the same range. (b) Pareto optimal solutions specified by 10 uniformly distributed reference vectors on a PF with objectives scaled different ranges. (c) Pareto optimal solutions specified by 10 adapted reference vectors on a PF with objectives scaled to different ranges.

Fig. 3. The Pareto optimal solutions (solid dots) specified by different reference vectors (dashed arrows) on different PF (solid lines).

- (1) Objective normalization, as a transformation that maps the objective values from a scaled objective space onto the normalized objective space, changes the actual objective values, which will further influence the selection criterion, i.e., the angle penalized distance.
- (2) Objective normalization has to be repeatedly performed as the scales of the objective values change in each generation.

As a consequence, performing objective normalization will cause instability in the convergence of the proposed RVEA due to the frequently changed selection criterion.

Nevertheless, it should be noted that although objective normalization is not suited for the proposed RVEA, it can work well for dominance based approaches such as NSGA-III, because the transformation does not change the partial orders, i.e., the dominance relations, between the candidate solutions, which is vital in dominance based approaches.

To illustrate the discussions above, we show below an empirical example. Given two translated objective vectors, $\mathbf{f}'_1 = (0.1, 2)$ and $\mathbf{f}'_2 = (1, 10)$, where \mathbf{f}'_1 dominates \mathbf{f}'_2 ; after objective normalization, the two vectors become $\bar{\mathbf{f}}'_1 = (0.1, 0.2)$ and $\bar{\mathbf{f}}'_2 = (1, 1)$. It can be seen that the dominance relation is not changed, where $\bar{\mathbf{f}}'_1$ still dominates $\bar{\mathbf{f}}'_2$. However, the difference between the two vectors has been substantially changed, from $\|\mathbf{f}'_2 - \mathbf{f}'_1\| = 8.0$ to $\|\bar{\mathbf{f}}'_2 - \bar{\mathbf{f}}'_1\| = 1.2$. It is very likely such a substantial change will influence the results generated by the angle penalized distance in (8), thus causing instability in the selection process.

Therefore, instead of normalizing the objectives, we propose to adapt the reference vectors according to the ranges of the objective values in the following manner:

$$\mathbf{v}_{t+1,i} = \frac{\mathbf{v}_{0,i} \odot (\mathbf{z}_{t+1}^{max} - \mathbf{z}_{t+1}^{min})}{\|\mathbf{v}_{0,i} \odot (\mathbf{z}_{t+1}^{max} - \mathbf{z}_{t+1}^{min})\|}, \quad (11)$$

where $i = 1, \dots, N$, $\mathbf{v}_{t+1,i}$ denotes the i -th adapted reference vector for the next generation $t + 1$, $\mathbf{v}_{0,i}$ denotes the i -th uniformly distributed reference vector, which is generated in the initialization stage (on Line 1 in Algorithm 1), \mathbf{z}_{t+1}^{max} and \mathbf{z}_{t+1}^{min} denote the maximum and minimum values of each objective function in the $t + 1$ generation, respectively. The

\odot operator denotes the Hadamard product that element-wisely multiplies two vectors (or matrices) of the same size.

With the reference vector adaptation strategy described above, the proposed RVEA will be able to obtain uniformly distributed solutions, even if the objective functions are not normalized to the same range, as illustrated in Fig. 3(c). Furthermore, some empirical results on the influence of the reference vector adaption strategy can be found in Appendix II.

Algorithm 3 The reference vector adaptation strategy in the proposed RVEA.

- 1: **Input:** generation index t , population P_{t+1} , current unit reference vector set $V_t = \{\mathbf{v}_{t,1}, \mathbf{v}_{t,2}, \dots, \mathbf{v}_{t,N}\}$, initial unit reference vector set $V_0 = \{\mathbf{v}_{0,1}, \mathbf{v}_{0,2}, \dots, \mathbf{v}_{0,N}\}$;
- 2: **Output:** reference vector set V_{t+1} for next generation;
- 3: **if** $(\frac{t}{t_{max}} \bmod f_r) == 0$ **then**
- 4: Calculate the minimal and maximal objective values \mathbf{z}_{t+1}^{min} and \mathbf{z}_{t+1}^{max} , respectively;
- 5: **for** $i = 1$ to N **do**
- 6: $\mathbf{v}_{t+1,i} = \frac{\mathbf{v}_{0,i} \odot (\mathbf{z}_{t+1}^{max} - \mathbf{z}_{t+1}^{min})}{\|\mathbf{v}_{0,i} \odot (\mathbf{z}_{t+1}^{max} - \mathbf{z}_{t+1}^{min})\|}$; //refer to (11);
- 7: **end for**
- 8: **else**
- 9: $\mathbf{v}_{t+1,i} = \mathbf{v}_{t,i}$;
- 10: **end if**

However, as pointed out by Giagkiozis *et al.* in [63], the reference vector adaptation strategy should not be employed very frequently during the search process to ensure a stable convergence. Fortunately, unlike objective normalization, the reference vector adaptation does not have to be performed in each generation. Accordingly, a parameter f_r (Line 3 in Algorithm 3) is introduced to control the frequency of employing the adaptation strategy. For instance, if f_r is set to 0.2, the reference vector will only be adapted at generation $t = 0$, $t = 0.2 \times t_{max}$, $t = 0.4 \times t_{max}$, $t = 0.6 \times t_{max}$ and $t = 0.8 \times t_{max}$, respectively. The detailed sensitivity analysis of f_r can be found in Supplementary Materials III.

Note that since the proposed reference vector adaptation strategy is only motivated to deal with problems with scaled objectives, it does not guarantee a uniform distribution of

the reference vectors on any type of PFs, especially on those with irregular geometrical features, e.g., disconnection or degeneration. In order to handle such irregular PFs, we have proposed another reference vector regeneration strategy in Section VI. Nevertheless, it is conceded that the proposed reference vector adaptation (as well as regeneration) strategy is not able to comfortably handle all specific situations, e.g., when a PF has low tails or sharp peaks [64].

E. Computational Complexity of the Proposed RVEA

To analyze the computational complexity of the proposed RVEA, we consider the main steps in one generation in the main loop of Algorithm 1. Apart from genetic operations such as crossover and mutation, the main computational cost is resulted from the reference vector guided selection procedure and the reference vector adaptation mechanism.

As shown in Algorithm 2, the reference vector guided selection procedure consists of the following components: objective value translation, population partition, angle-penalized distance (APD) calculation and elitism selection. We will see that the computational complexity of each component is very low, as will be analyzed in the following. The time complexity for the objective value translation is $O(MN)$, where M is the objective number and N is the population size. The time complexity for population partition is $O(MN^2)$. In addition, calculation of APD and elitism selection hold a computational complexity of $O(MN^2)$ and $O(N^2)$ in the worst case, respectively. Finally, the computational complexity for the reference vector adaptation procedure is $O(MN/(f_r \cdot t_{max}))$, where f_r and t_{max} denote the frequency to employ the reference vector adaptation strategy and maximal number of generations, respectively.

To summarize, apart from the genetic variations, the worst-case overall computational complexity of RVEA within one generation is $O(MN^2)$, which indicates that RVEA is computationally efficient.

IV. COMPARATIVE STUDIES

In this section, empirical experiments are conducted on 15 benchmark test problems taken from two widely used test suites, i.e., the DTLZ [65] test suite (including the scaled version [36]) and the WFG test suite [62], to compare RVEA with five state-of-the-art MOEAs for many-objective optimization, namely, MOEA/DD [38], NSGA-III [36], MOEA/D-PBI [27], GrEA [22], and KnEA [26]. For each test problem, objective numbers varying from 3 to 10, i.e., $M \in \{3, 6, 8, 10\}$ are considered.

In the following subsections, we first present a brief introduction to the benchmark test problems and the performance indicator used in our comparative studies. Then, the parameter settings used in the comparisons are given. Then, each algorithm is run for 20 times on each test problem independently, and the Wilcoxon rank sum test is adopted to compare the results obtained by RVEA and those by five compared algorithms at a significance level of 0.05. Symbol '+' indicates that the compared algorithm is significantly outperformed by RVEA according to a Wilcoxon rank sum

test, while '-' means that RVEA is significantly outperformed by the compared algorithm. Finally, ' \approx ' means that there is no statistically significant difference between the results obtained by RVEA and the compared algorithm.

A. Benchmark Test Problems

The first four test problems are DTLZ1 to DTLZ4 taken from the DTLZ test suite [65]. As recommended in [65], the number of decision variables is set to $n = M + K - 1$, where M is the objective number, $K = 5$ is used for DTLZ1, $K = 10$ is used for DTLZ2, DTLZ3 and DTLZ4.

We have also used the scaled version of the DTLZ1 and DTLZ3 (denoted as SDTLZ1 and SDTLZ3) for comparisons to see if the proposed RVEA is capable of handling strongly scaled problems. The scaling approach is recommended in [36], where each objective is multiplied by a coefficient p^{i-1} , where p is a parameter that controls the scaling size and $i = 1, \dots, M$ is the objective index. For example, given $p = 10$, the objectives of a 3-objective problem will be scaled to be $10^0 \times f_1$, $10^1 \times f_2$ and $10^2 \times f_3$. In our experiments, the values of p are set to 10, 5, 3, 2 for problems with an objective number $M = 3, 6, 8, 10$, respectively.

The other nine test problems are WFG1 to WFG9 taken from the WFG test suite [62], [66], which are designed by introducing difficulties in both the decision space (e.g. non-separability, deception and bias) and the objective space (e.g. mixed geometrical structures of the PFs). As suggested in [62], the number of decision variables is set as $n = K + L - 1$, where M is the objective number, the distance-related variable $L = 10$ is used in all test problems, and the position-related variable $K = 4, 10, 7, 9$ are used for test problems with $M = 3, 6, 8, 10$, respectively.

B. Performance Indicators

To make empirical comparisons between the results obtained by each algorithm, the hypervolume (HV) [43] is used as the performance indicator in the comparisons.

Let $y^* = (y_1^*, \dots, y_M^*)$ be a reference point in the objective space that is dominated by all Pareto optimal solutions, and P be the approximation to PF obtained by an MOEA. The HV value of P (with respect to y^*) is the volume of the region which dominates y^* and is dominated by P .

In this work, $y^* = (1.5, 1.5, \dots, 1.5)$ is used for DTLZ1, SDTLZ1; $y^* = (2, 2, \dots, 2)$ is used for DTLZ2, DTLZ3, SDTLZ3, DTLZ4; and $y^* = (3, 5, \dots, 2M + 1)$ is used for WFG1 to WFG9. For problems with fewer than 8 objectives, the recently proposed fast hypervolume calculation method is adopted to calculate the exact hypervolume [67], while for 8-objective and 10-objective problems, the Monte Carlo method [40] with 1,000,000 sampling points is adopted to obtain the approximate hypervolume values. All hypervolume values presented in this work are all normalized to $[0, 1]$ by dividing $\prod_{i=1}^m y_i^*$.

C. Parameter Settings

In this subsection, we first present the general parameter settings for the experiments, and afterwards, the specific parameter settings for each algorithm in comparison are given.

TABLE I
SETTINGS OF POPULATION SIZES IN RVEA, MOEA/DD, NSGA-III AND MOEA/D-PBI.

M	(H_1, H_2)	Population size
3	(13, 0)	105
6	(4, 1)	132
8	(3, 2)	156
10	(3, 2)	275

H_1 and H_2 are the simplex-lattice design factors for generating uniformly distributed reference (or weight) vectors on the outer boundaries and the inside layers, respectively.

TABLE II
PARAMETER SETTING OF *div* IN GrEA ON EACH TEST INSTANCE

Problem	M = 3	M = 4	M = 6	M = 8	M = 10
DTLZ1	16	10	10	10	11
DTLZ2	15	10	10	8	12
DTLZ3	17	11	11	10	11
DTLZ4	15	10	8	8	12
SDTLZ1	16	10	10	10	11
SDTLZ3	17	11	11	10	11
WFG1	10	8	9	7	10
WFG2	12	11	11	11	11
WFG3	22	18	18	16	22
WFG4-9	15	10	9	8	12

1) *Settings for Crossover and Mutation Operators*: For the simulated binary crossover [59], the distribution index is set to $\eta_c = 30$ in RVEA, MOEA/DD and NSGA-III, $\eta_c = 20$ in the other four algorithms, and the crossover probability $p_c = 1.0$ is used in all algorithms; for the polynomial mutation [60], the distribution index and the mutation probability are set to $\eta_m = 20$ and $p_m = 1/n$, respectively, as recommended in [68].

2) *Population Size*: For RVEA, MOEA/DD, NSGA-III and MOEA/D-PBI, the population size is determined by the simplex-lattice design factor H together with the objective number M , referring to (2). As recommended in [36], [38], for problems with $M \geq 8$, a two-layer vector generation strategy can be applied to generate reference (or weight) vectors not only on the outer boundaries but also on the inside layers of the Pareto fronts. The detailed settings of the population sizes in RVEA, MOEA/DD, NSGA-III and MOEA/D-PBI are summarized in Table I. For the other two algorithms, GrEA and KnEA, the population sizes are also set according to Table I, with respect to different objective numbers M .

3) *Termination Condition*: The termination condition of each run is the maximal number of generations. For DTLZ1, SDTLZ1, DTLZ3, SDTLZ3 and WFG1 to WFG9, the maximal number of generations is set to 1000. For DTLZ2 and DTLZ4, the maximal number of generations is set to 500.

4) *Specific Parameter Settings in Each Algorithm*: For MOEA/D-PBI, the neighborhood size T is set to 20, and the penalty parameter θ in PBI is set to 5, as recommended in [27], [36]. For MOEA/DD, T and θ are set to the same values as in MOEA/D-PBI, and the neighborhood selection probability is set to $\delta = 0.9$, as recommended in [38]. For GrEA and KnEA, the detailed parameter settings are listed in Table II and Table III, respectively, which are all recommended settings by the authors [22], [26].

TABLE III
PARAMETER SETTING OF T IN KnEA ON EACH TEST INSTANCE

Problem	M = 3	M = 4	M = 6	M = 8	M = 10
DTLZ1	0.6	0.6	0.2	0.1	0.1
DTLZ3	0.6	0.4	0.2	0.1	0.1
SDTLZ1	0.6	0.6	0.2	0.1	0.1
SDTLZ3	0.6	0.4	0.2	0.1	0.1
others	0.5	0.5	0.5	0.5	0.5

Two parameters in RVEA require to be predefined, i.e., the index α used to control the rate of change of the penalty function in (9), and the frequency f_r to employ the reference vector adaptation in Algorithm 3. In the experimental comparisons, $\alpha = 2$ and $f_r = 0.1$ is used for all test instances. A sensitivity analysis of α and f_r is provided in Supplementary Materials III.

In order to reduce the time cost of non-dominated sorting, the efficient non-dominated sorting approach ENS-SS reported in [69] has been adopted in NSGA-III, GrEA and KnEA, and a steady-state non-dominated sorting approach as reported in [70] has been adopted in MOEA/DD. By contrast, neither RVEA nor MOEA/D-PBI uses dominance comparisons. All the algorithms are realized in Matlab R2012a except MOEA/DD, which is implemented in the jMetal framework [71].

D. Performance on DTLZ1 to DTLZ4, SDTLZ1 and SDTLZ3

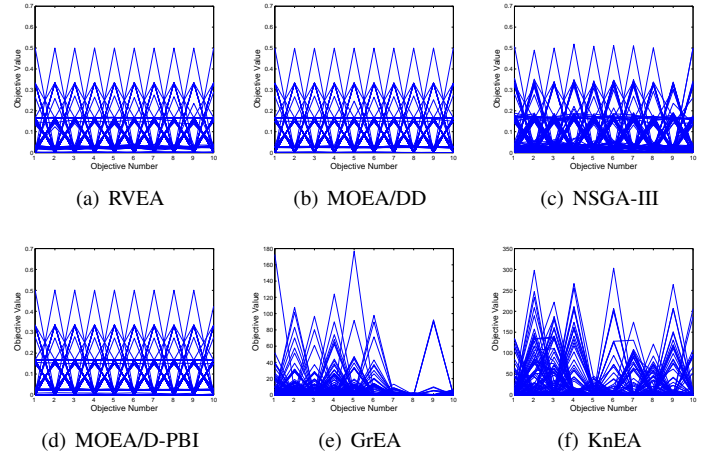

Fig. 4. The parallel coordinates of non-dominated front obtained by each algorithm on 10-objective DTLZ1 in the run associated with the median HV value.

The statistical results of the HV values obtained by the six algorithms over 20 independent runs are summarized in Table IV, where the best results are highlighted. It can be seen that RVEA, together with MOEA/DD, shows best overall performance among the six compared algorithms on the four original DTLZ test instances, while NSGA-III shows the best overall performance on the scaled DTLZ test instances.

As can be observed from Fig. 4, the approximate PFs obtained by RVEA, MOEA/DD and MOEA/D-PBI show promising convergence performance as well as a good distribution on 10-objective DTLZ1. The statistical results in Table IV

TABLE IV

THE STATISTICAL RESULTS (MEAN AND STANDARD DEVIATION) OF THE HV VALUES OBTAINED BY RVEA, MOEA/DD, NSGA-III, MOEA/D-PBI, GrEA AND KNEA ON DTLZ1 TO DTLZ4, SDTLZ1 AND SDTLZ3. THE BEST RESULTS ARE HIGHLIGHTED.

≈: There is no significant difference between the compared results.

Fig. 5. The parallel coordinates of non-dominated front obtained by each algorithm on 10-objective DTLZ4 in the run associated with the median HV value.

also indicate that RVEA, MOEA/DD and MOEA/D-PBI have achieved the best performance among the six algorithms on all DTLZ1 instances, where MOEA/DD shows best performance on 3-objective instance and RVEA shows best performance on 6-objective and 8-objective instances. Meanwhile, the PFs approximated by NSGA-III is also of high quality. By contrast, neither GrEA nor KnEA is able to converge to the true PF of 10-objective DTLZ1.

Similar observations can be made about the results on

DTLZ2, a relatively simple test problem, to those on DTLZ1. RVEA shows the best performance on the 8-objective instance, while MOEA/DD outperforms RVEA on 3-objective and 6-objective instances. NSGA-III and MOEA/D-PBI are slightly outperformed by RVEA. Compared to the performance on 10-objective DTLZ1, the performance of GrEA and KnEA on this instance is much better.

For DTLZ3, which is a highly multimodal problem, RVEA and MOEA/DD have also obtained an approximate PF of high quality. It seems that the performance of NSGA-III and MOEA/D-PBI is not very stable on high dimensional (8-objective and 10-objective) instances of this problem, as evidenced by the statistical results in Table IV, while GrEA and KnEA completely fail to reach the true PF of this problem.

DTLZ4 is test problem where the density of the points on the true PF is strongly biased. This test problem is designed to verify whether an MOEA is able to maintain a proper distribution of the candidate solutions. From the results, we can see that RVEA and MOEA/DD remain to show the best overall performance. By contrast, MOEA/D-PBI is generally outperformed by the other five algorithms. As can be observed from Fig. 5, it appears that MOEA/D-PBI is only able to find some parts of the true PF. The performance of NSGA-III is similar to that of RVEA. An interesting observation is that, although the distribution of the approximate PFs obtained by GrEA and KnEA look slightly noisy, the solutions are still relatively evenly distributed, and thus the HV values obtained by these two algorithms are very encouraging, especially on

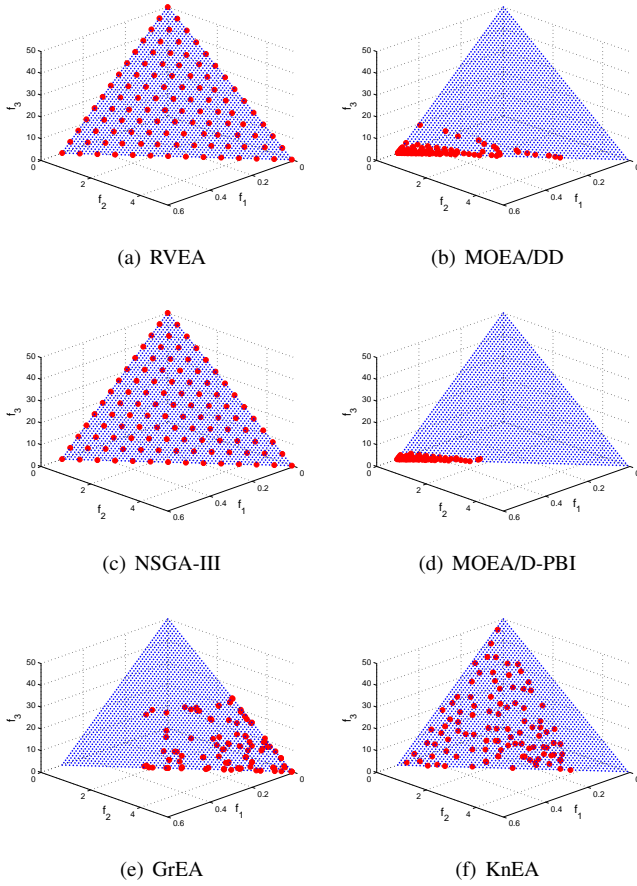

Fig. 6. The non-dominated solutions obtained by each algorithm on 3-objective SDTLZ1 in the run associated with the median HV value.

the 8-objective and 10-objective instances.

Compared with the original DTLZ problems, the SDTLZ1 and SDTLZ3 are challenging due to the strongly scaled objective function values. It turns out that NSGA-III shows the best overall performance on SDTLZ1, 3-objective and 6-objective SDTLZ3, while RVEA shows the best overall performance on 8-objective and 10-objective SDTLZ3. As shown in Fig. 6, RVEA and NSGA-III are the only two algorithms that are able to generate evenly distributed solutions on the 3-objective SDTLZ1, while the other four algorithms have all failed. Such observations are consistent with those reported in [36], where it has been shown that even the normalized version of MOEA/D still does not work on such scaled DTLZ problems.

E. Performance on WFG1 to WFG9

As evidenced by statistical results of the HV values summarized in Table V, RVEA has shown the most competitive performance on WFG4, WFG5, WFG6, WFG7 and WFG9, while MOEA/DD, NSGA-III, GrEA and GrEA have achieved the best performance on WFG8, WFG2, WFG3 and WFG1, respectively. By contrast, the performance of MOEA/D-PBI on the WFG test functions is not as good as that on the DTLZ test functions. In the following, some discussions on the experimental results will be presented.

WFG1 is designed with flat bias and a mixed structure of the PF. Although RVEA is slightly outperformed by GrEA and

KnEA, its performance is still significantly better than NSGA-III and MOEA/D-PBI. WFG2 is a test problem which has a disconnected PF. It can be observed that although the HV values obtained by each algorithm vary on this test problem, the overall performance is generally very good. More specifically, the overall performance of RVEA is better than MOEA/D-PBI and GrEA, while NSGA-III has achieved the best overall performance. WFG3 is a difficult problem where the PF is degenerate and the decision variables are non-separable. On this problem, RVEA has achieved comparable higher HV values than MOEA/D-PBI, but has been outperformed by the other four algorithms, where GrEA has achieved the largest HV values on all the instances of this problem.

WFG4 to WFG9 are designed with different difficulties in the decision space, e.g., multimodality for WFG4, landscape deception for WFG5 and non-separability for WFG6, WFG8 and WFG9, though the true PFs are of the same convex structure. As can be observed in Table V, RVEA shows the most competitive overall performance on these six problems by achieving the best results on 14 out of 24 instances. By contrast, GrEA shows high effectiveness on most 3-objective instances, KnEA shows promising performance on some 8-objective and 10-objective instances; MOEA/DD and NSGA-III also show generally competitive performance.

F. Comparisons between APD, TCH and PBI

In principle, most scalarization approaches used in the decomposition based MOEAs are also applicable to the proposed RVEA. In this section, we will carry out some comparative studies on the original RVEA, RVEA with the weighted Tchebycheff (TCH) approach [52], and RVEA with the penalty-based boundary intersection (PBI) approach [50]. The detailed definitions of the scalarization functions of TCH approach and PBI approach can be found in the Supplementary Materials IV.

In order to apply the TCH and PBI approaches in RVEA, we simply replace the weight vectors with the reference vectors, and then replace the APD part (between Line 19 to Line 23 in Algorithm 2) with the two approaches. For simplicity, RVEA with the TCH and PBI approaches are denoted as RVEA-TCH and RVEA-PBI, respectively.

The performance of RVEA-TCH and RVEA-PBI has been verified on six benchmark test problems selected from different test suites, including DTLZ1, DTLZ3, SDTLZ1, SDTLZ3, WFG4 and WFG5. The results are compared with those obtained by the original RVEA. As shown by the statistical results summarized in Table VI, RVEA shows the best performance on SDTLZ1, SDTLZ3, WFG4, WFG5, and significantly outperforms RVEA-TCH on DTLZ1 and DTLZ3.

It is also observed that RVEA-PBI shows very close performance to RVEA on the original DTLZ problems (DTLZ1 and DTLZ3), but is completely outperformed on the scaled DTLZ problems (SDTLZ1 and SDTLZ3). It implies that the proposed APD has better capability of handling strongly scaled problems than PBI. The superiority of APD over PBI can be attributed to two main reasons. One is that the penalty function in APD is relatively insensitive to the ranges (either scaled or

not) of the objective functions, as the penalty function is angle (instead of distance) based, where the angle is normalized inside each subspace according to the local density of the reference vectors. The other is that the adaptive strategy in APD emphasizes the convergence at the initial search stage, which is particularly helpful when the objective vectors are scaled to be distant from the ideal point.

V. PREFERENCE ARTICULATION

Fig. 7. A visualized illustration of the transformation procedure to generate reference vectors inside a region specified by a central vector \mathbf{v}_c and a radius r . In this example, 10 uniformly distributed reference vectors are generated inside a region in a bi-objective space specified by $\mathbf{v}_c = (\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2})$ and $r = 0.5$.

(c) The approximate Pareto optimal solutions distributed on the corners of the PF of DTLZ2. (d) The approximate Pareto optimal solutions distributed on the center of the PF of DTLZ2.

Fig. 8. The preferred Pareto optimal solutions approximated by RVEA on DTLZ1 and DTLZ2 with reference vectors articulated with different preferences.

The proposed RVEA, a method based on reference vectors, is inherently capable of articulating user preferences. Preference articulation is particularly meaningful in many-objective optimization as we can no longer obtain a good (representative) approximation of a high-dimensional PF using a limited population size.

In comparison with the reference point based preference articulation methods [36], [55]–[57], reference vector based preference articulation is more intuitive, as each reference vector specifies a line instead of a point, which means that the Pareto optimal solutions can always be found by RVEA as long as there exists one along the direction specified by the reference vector, regardless where the solution is exactly located. In this section, we will demonstrate the ability of RVEA in preference articulation by providing a few illustrative examples on the 3-objective DTLZ1 and DTLZ2.

To begin with, a preference based reference vector generation method is proposed to uniformly generate reference vectors in a user specified subspace of the objective space. To specify a preferred subspace, a user may first identify a central vector \mathbf{v}_c and a radius r , where \mathbf{v}_c is a unit vector and $r \in (0, 1)$. Then, the reference vectors inside the subspace can be generated using the following transformation:

$$\mathbf{v}_i' = \frac{r \cdot \mathbf{v}_i + (1-r) \cdot \mathbf{v}_c}{\|r \cdot \mathbf{v}_i + (1-r) \cdot \mathbf{v}_c\|}, \quad (12)$$

where $i = 1, \dots, N$ is the index of each reference vector, \mathbf{v}_i denotes a uniformly distributed vector generated with (2) and (3), and \mathbf{v}_i' denotes a reference vector transformed from \mathbf{v}_i , which is inside the subspace specified by \mathbf{v}_c and r . A visualized illustration of the above transformation procedure can be found in Fig. 7. With such a preference based reference vector generation method, we are now able to generate uniformly distributed reference vectors inside the preferred subspaces in the objective space.

Firstly, we show an example where the reference vectors are distributed in the corners of the objective space of DTLZ1 and DTLZ2, as shown in Fig. 8(a) and Fig. 8(c). In this example, 10 preference vectors are uniformly generated in each corner of the objective space by setting $\mathbf{v}_c = \{(0, 0, 1), (0, 1, 0), (1, 0, 0)\}$ and $r = 0.2$. As a consequence, RVEA has successfully obtained all the solutions specified by the reference vectors on both test problems.

The second example is to examine if RVEA is capable of dealing with preferences in the center of the objective space. As shown in Fig. 8(b) and Fig. 8(d), the 10 solutions obtained by RVEA show good convergence as well as distribution. This example also implies that RVEA is still able to work effectively with a very small population size, even on a difficult multimodal problem like DTLZ1. In this example, reference vectors are generated with $\mathbf{v}_c = (\frac{\sqrt{3}}{3}, \frac{\sqrt{3}}{3}, \frac{\sqrt{3}}{3})$ and $r = 0.2$.

It is worth noting that we have not changed any settings in RVEA to obtain the preferred solutions shown above, except that the reference vector adaptation procedure (on Line 10 in Algorithm 1) has been switched off, such that the distribution of the reference vectors specified by the user preferences will not be changed during the search process. Another point to note is that the extreme vectors, i.e., $(0, 0, 1)$, $(0, 1, 0)$ and

(1, 0, 0) in the 3-objective case are always included, because the translation operation, as introduced in Section III-C1, requires the extreme values of each objective function.

VI. HANDLING IRREGULAR PARETO FRONTS

Algorithm 4 The reference vector regeneration strategy for handling irregular Pareto fronts.

```

1: Input: population  $P_t$ , the additional reference vector set
    $V_t^* = \{\mathbf{v}_{t,1}^*, \mathbf{v}_{t,2}^*, \dots, \mathbf{v}_{t,N}^*\}$ ;
2: Output: the additional reference vector set  $V_{t+1}^*$  for next
   generation;
3: Remove the dominated solutions in  $P_t$ ;
4: /*Objective Value Translation*/
5: Perform objective value translation using the operations
   from Line 4 to Line 7 in Algorithm 2;
6: /*Population Partition*/
7: Perform population partition using the operations from
   Line 9 to Line 17 in Algorithm 2;
8: /*Reference Vector Regeneration*/
9: Calculate maximal objective values  $\mathbf{z}_t^{max}$ ;
10: for  $i = 1$  to  $|V_t^*|$  do
11:   if  $\bar{P}_{t,i} == \emptyset$  then
12:     for  $j = 1$  to  $N$  do
13:        $\mathbf{u}_{r,j} \leftarrow$  a value randomized within  $[0, \mathbf{z}_{t,j}^{max}]$ ;
14:     end for
15:      $\mathbf{v}_{t+1,i}^* = \frac{\mathbf{u}_r}{\|\mathbf{u}_r\|}$ ;
16:   else
17:      $\mathbf{v}_{t+1,i}^* = \mathbf{v}_{t,i}^*$ ;
18:   end if
19: end for

```

As presented in Section IV, the proposed RVEA is able to perform robustly on a variety of test problems with a set of uniformly distributed reference vectors. In fact, using uniform distributed reference vectors is based on a general assumption that the PF has a regular geometrical structure, i.e., it is smooth, continuous and well spread. However, in practice, the geometrical structure of a PF can be quite irregular due to various reasons. For example, some parts of the objective space are infeasible due to some constraints, or the Pareto optimal solutions only exist in some specific subspaces in the objective space while the other subspaces only contain dominated solutions. In these cases, the PFs can become disconnected or even degenerate. On such problems, if we still use uniformly distributed reference vectors, some of the reference vectors may be associated with no individuals (termed invalid reference vectors hereafter), thus considerably reducing the density of the Pareto optimal solutions obtained by RVEA.

To tackle the issue caused by irregular PFs as discussed above, one intuitive idea is to regenerate the invalid reference vectors, as adopted in some existing adaptive approaches for generating reference points [72], [73] as well as reference vectors [53] and weight vectors [74], [75]. However, one difficulty is that we have no idea when the regeneration procedure should be carried out, because even for a regular PF,

it is still likely that some reference vectors can be occasionally invalid during the search process. To guarantee a wide spread in the distribution of the candidate solutions, as suggested in the reference point adaptation strategy for NSGA-III [72], the original uniformly distributed reference point set should always be maintained, and some new reference points can be added in the neighborhood of each existing reference point. A newly added reference point will be included in the reference point set if and only if it has a niche count of one. A merit of this adaptive approach is that the new reference points are added in the neighborhood of existing reference points, while a potential demerit is that although a large number of reference points are added in each generation, only a small portion of them can survive, since the sum of niche count is always N . This reduces the efficiency of the algorithm.

In this work, we also propose to maintain the original uniform reference vector set V , while an additional reference vector set (denoted as V^*) is introduced to perform exploration for handling the irregular Pareto fronts. Compared to the reference point adaptive strategy in NSGA-III, the proposed reference vector regeneration strategy is based on "replacement", instead of "addition-and-deletion", which results in higher efficiency. However, since the reference vectors are generated globally, the local solution density is not guaranteed, which can be a potential disadvantage.

The detailed procedure of the proposed reference vector regeneration strategy is summarized in Algorithm 4. At the beginning, all the dominated solutions in the current population are removed. Afterwards, the objective value translation and population partition operations are performed. Based on the result of the population partition, for each empty subpopulation, the associated reference vector will be replaced with a unit

vector, which is randomly generated inside the range specified by the minimum⁵ and maximum objective values calculated from the candidate solutions in the current population; while for the nonempty subpopulations, the associated reference vectors will remain unchanged. To use the reference vector regeneration strategy in RVEA, the only minor modification needed is to insert Algorithm 4 into the end of the main loop (between Line 10 and Line 11) in Algorithm 1, and in each generation, $V_t \cup V_t^*$ (instead V_t) can be used to guide the elitism selection performed in Algorithm 2.

To assess the performance of the proposed reference vector regeneration strategy, empirical experiments are conducted on three typical test problems having irregular PFs, i.e., DTLZ5, DTLZ6 and DTLZ7. Specifically, DTLZ5 and DTLZ6 have a degenerate PF, which is always a 2-dimensional curve in the hyperspace, regardless of the number of objectives; DTLZ7 has a disconnected PF, where the number of segments can be as large as 2^{M-1} , and M is the number of objectives.

+ : RVEA* shows significantly better performance in the comparison.

In the experiments, the RVEA embedded with the reference vector regeneration strategy (denoted as RVEA* hereafter) is compared with the original RVEA. To measure the quality of the solutions obtained by RVEA* and RVEA, the HV indicator is used, and the reference points used in the HV calculation are set as $(z_1^{max} + 1, z_2^{max} + 1, \dots, z_M^{max} + 1)$, where z_1^{max} to z_M^{max} are the maximum objective values calculated from the true PF⁶ of each test problem. All the HV values are normalized to $[0, 1]$. For fair comparisons, an additional reference vector set is also added to RVEA, where all the reference vectors are randomly initialized, though they do not undergo the reference vector regeneration strategy in each generation.

As shown in Table VII and Fig. 9, RVEA*, in which the reference vector regeneration strategy is embedded, significantly outperforms the original RVEA on all test instances.

⁵Since the objective values have already been translated, the minimum value of each objective is always 0.

⁶Since the PFs of DTLZ5, DTLZ6 and DTLZ7 have an irregular geometrical structure, the true PFs are approximated by sampling 10000 Pareto optimal solutions in the decision space.

VII. HANDLING CONSTRAINTS

The proposed RVEA has shown competitive performance on a variety of unconstrained optimization problems. However, constrained optimization problems are widely seen in solving practical problems. Therefore, in this section, we extend RVEA to handling constraints (denoted as C-RVEA) by making some minor modifications to the selection strategy in Algorithm 2. The performance of C-RVEA is assessed on three representative constrained problems in comparison with C-MOEA/DD, which is the constrained version of MOEA/DD [38].

To begin with, the constraint violation function suggested in [72] is adopted to evaluate the degree of violation of a candidate solution:

$$CV(\mathbf{x}) = \sum_{j=1}^J \langle g_j(\mathbf{x}) \rangle + \sum_{k=1}^K |h_k(\mathbf{x})|, \quad (13)$$

where $g_j \geq 0$ and $h_j = 0$ are constraints, the operator $\langle \alpha \rangle$ returns a negative value of α if $\alpha < 0$, and returns 0 otherwise.

Algorithm 5 The elitism selection strategy for handling constraints.

```

1: for  $j = 1$  to  $N$  do
2:    $S = \emptyset$ ; // index set of infeasible solutions
3:   for  $i = 1$  to  $|\bar{P}_{t,j}|$  do
4:     if  $CV(\mathbf{x}_{t,i}) > 0$  then
5:        $S = S \cup \{i\}$ 
6:     end if
7:   end for
8:   if  $|S| == |\bar{P}_{t,j}|$  then
9:      $k = \operatorname{argmin}_{i \in \{1, \dots, |\bar{P}_{t,j}|\}} CV(\mathbf{x}_{t,i})$ 
10:  else
11:     $k = \operatorname{argmin}_{i \in \{1, \dots, |\bar{P}_{t,j}|\}, i \notin S} d_{t,i,j}$ 
12:  end if
13:   $P_{t+1} = P_t \cup \{I_{t,k}\}$ ;
14: end for
    
```

As summarized in Algorithm 5, the basic idea of the elitism selection strategy for handling constraints is to take the constraint violations into consideration in the selection process. Firstly, we pick out the infeasible solutions and record the indices in S . Afterwards, we check the size of S . If the size of S equals that of the current subpopulation $\bar{P}_{t,j}$, which means that every solution is infeasible, we will select the one having the minimum degree of constraint violation to be passed to the next generation; otherwise, we select the one with the minimal APD value among the feasible solutions.

In order to assess the performance of the proposed elitism selection strategy for handling constraints, empirical studies have been conducted on three representative constrained problems, namely, C1-DTLZ1, C2-DTLZ2 and C3-DTLZ3, where the detailed definitions of the constraints can be found in Supplementary Materials V.

Both C-RVEA and C-MOEA/DD are run 20 times independently on each test instance. In each single run, 1000 generations are run for C1-DTLZ1, and 500 generations for

TABLE VIII

+ : RVEA shows significantly better performance in the comparison.
 − : RVEA shows significantly worse performance in the comparison.
 ≈ : There is no significant difference between the compared results.

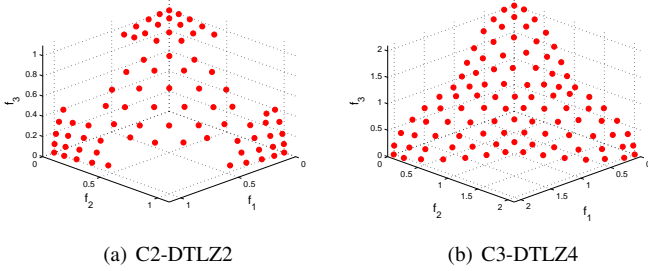

Fig. 10. The approximate Pareto optimal solutions obtained by C-RVEA on the 3-objective C2-DTLZ2 and C3-DTLZ4 in the run associated with the median HV values.

C2-DTLZ2, C3-DTLZ4. We again use the HV as the performance indicator, and the reference points for C1-DTLZ1, C2-DTLZ2 and C3-DTLZ4 are $(1.5, 1.5, \dots, 1.5)$, $(2, 2, \dots, 2)$ and $(3, 3, \dots, 3)$, respectively.

Generally speaking, C-RVEA and C-MOEA/DD show comparable performance, as shown by the results in Table VIII. Specifically, C-RVEA outperforms C-MOEA/DD on C1-DTLZ1, but is outperformed on C3-DTLZ4, and the two algorithms show comparable performance on C2-DTLZ2. In addition to the statistical results, the approximate Pareto optimal solutions obtained by C-RVEA on the 3-objective C2-DTLZ2 and C3-DTLZ4 are plotted in Fig. 10.

VIII. CONCLUSION

In this paper, we have proposed a reference vector based MOEA, termed RVEA, for solving MaOPs. In the proposed RVEA, the search process is guided by a set of predefined reference vectors inspired from the direction vectors proposed in MOEA/D-M2M, a decomposition based approach. The basic idea is to partition the objective space into a number small subspaces using a set of reference vectors. Inside each subspace, an elitism selection strategy is employed. As the selection criterion, a scalarization approach, known as the angle-penalized distance (APD), is proposed to measure the distance of the solutions to the ideal point and the closeness of the solutions to the reference vectors, which can be seen as a

diversity measure or a degree of satisfaction to the preferences. Thus, the proposed RVEA can be largely categorized into the decomposition based approaches, when the reference vectors are uniformly generated to cover the whole PF. On the other hand, the proposed RVEA is also able to find a set of preferred Pareto optimal set, which can be used for elucidation of user preferences. We demonstrate that reference vectors are well suited for precise preference articulation by defining a central vector and a radius. The effectiveness of the reference vector based preference articulation is demonstrated by some illustrative empirical examples.

To obtain a set of uniformly distributed solutions in the objective space, a strategy for adapting the reference vectors has been suggested to tune the reference vectors according to the distribution of the candidate solutions. This reference vector adaptation strategy has shown high efficiency in dealing with problems where the objective functions are not well normalized.

To assess the performance of RVEA, empirical comparisons have been conducted by comparing RVEA with five state-of-the-art MOEAs, namely, MOEA/DD, NSGA-III, MOEA/D-PBI, GrEA and KnEA on widely used MaOP test functions. Our experimental results indicate that RVEA shows robust performance on various benchmark problems with the objective number varying from 3 to 10, including normalized DTLZ problems, scaled DTLZ problems, and WFG problems. We have also conducted some experiments to compare the performance of APD with two popular scalarization approaches widely used in the decomposition based MOEAs, i.e., the Weighted Tchebycheff approach and the PBI approach.

Furthermore, a reference vector regeneration strategy has been proposed to improve the performance of RVEA on problems with irregular Pareto fronts. The strategy can be inserted into the framework of RVEA and shows high effectiveness. Finally, RVEA has been extended for solving constrained MaOPs.

The proposed RVEA has shown competitive performance on the studied MaOP test problems. One interesting feature of the proposed RVEA is that it is able to approximate the Pareto optimal solutions specified by the predefined reference vectors when the PF distributes in the whole objective space. However, the question remains open as to how the reference vectors can be adapted to the distribution of the candidate solutions according to the estimated geometrical features of the PF. It is still unclear which type of reference vectors is most practical in many-objective optimization. In addition, the use of reference vectors for interactive preference articulation is to be investigated [76].

Supplementary Materials

I. SIGNIFICANCE OF THE OBJECTIVE VALUE TRANSLATION

In this subsection, we will discuss the significance of the objective value translation by showing some empirical results.

Fig. 1. An example to show the intersection points between 10 uniformly distributed reference vectors and the PF of bi-objective DTLZ7 before (denoted as F) and after (denoted as F') the objective value translation.

For simplicity, we choose the bi-objective DTLZ7 to conduct the empirical studies. As shown in Fig. 1, before the objective value translation, there are only two intersection points between the ten reference vectors and the PF F , while after objective value translation, the number of the intersection points has increased to nine.

Fig. 2. The approximate Pareto optimal solutions obtained by RVEA on the bi-objective DTLZ7 with and without the objective value translation, respectively.

Further observations can be found in Fig. 2(a) and Fig. 2(b), where the approximate Pareto optimal solutions are obtained by RVEA on the bi-objective DTLZ7 with and without the objective value translation, respectively. As a consequence, it can be observed that objective value translation is able to significantly increase the density of the Pareto optimal solutions approximated by RVEA.

II. INFLUENCE OF THE REFERENCE VECTOR ADAPTATION

The reference vector adaptation strategy is able to adjust the reference vectors according to the distribution of the objective values of the candidate solutions. We present here some additional results in order to further verify its effectiveness.

For the sake of easy visualization, the 3-objective WFG7, where the PF is distributed as $f_1 \in [0, 2]$, $f_2 \in [0, 4]$ and $f_3 \in [0, 6]$, is used to conduct the empirical studies. For comparison, we switch off the reference vector adaptation mechanism, i.e., the reference vectors will remain uniformly distributed. However, as shown in Fig 3(b), the candidate solutions specified by the reference vectors do not show a uniform distribution. By contrast, after switching on the reference vector adaptation mechanism so that the reference vectors will be dynamically adjusted according to the distribution of the objective values, as a consequence, the candidate solutions obtained by RVEA distribute uniformly, as evident from Fig. 3(a).

(a) The approximate Pareto optimal solutions obtained with reference vector adaptation being switched on. (b) The approximate Pareto optimal solutions obtained with reference vector adaptation being switched off.

Fig. 3. The Pareto optimal solutions approximated by RVEA on the 3-objective WFG7 when the reference vector adaptation procedure is switched on and off, respectively.

III. PARAMETER SENSITIVITY ANALYSIS

There are two parameters to be specified by the user in RVEA, i.e., α that controls the rate of change of the penalty function $P(\theta)$, and f_r that controls the frequency to employ the reference vector adaptation. In this subsection, to further investigate the sensitivity of the performance of RVEA to the settings of α and f_r , additional optimization runs are performed with various settings of α and f_r on DTLZ3 and WFG4, which are selected from the DTLZ suite and the WFG test suite, respectively.

We first carry out sensitivity analysis of parameter α . Three observations can be made from the results plotted in 4, where f_r is fixed to 0.1 and α varies from 1 to 9. The first observation is that the performance of RVEA on DTLZ3, which is a normalized optimization problem, is insensitive to the settings of α . The second observation is that, on 6-objective, 8-objective and 10-objective WFG4, which is a

Fig. 4. The HV values obtained by RVEA averaged over 20 independent runs with f_r fixed to 0.1 and α varying from 1 to 9.

scaled problem, the performance of RVEA starts to slightly deteriorate with the increase of α after α is larger than 3. It implies that, in high-dimensional scaled objective space, where the candidate solutions are sparsely distributed, a relatively smaller α is very helpful in maintaining a proper population diversity. The third observation is that on 3-objective WFG4, a larger α generates better optimization results. This observation implies that in low-dimensional objective space, where the candidate solutions are densely distributed, emphasizing the population convergence using a larger α will help further improve the solution quality. Based on the above observations, we can conclude that the performance of RVEA is in general insensitive to the settings of α , and a small α is preferred if the population diversity requires to be enhanced, while a large α can be used to emphasize the population convergence.

Fig. 5. The HV values obtained by RVEA averaged over 20 independent runs with α fixed to 2 and f_r varying from 0.01 to 0.5.

Sensitivity analysis of f_r is carried out by fixing α to 2 and varying f_r from 0.01 to 0.5. For any $f_r \geq 0.5$, the reference vector adaptation will only be employed twice, once at the initial generation and the other at the $(f_r \times t_{max})$ -th generation. It turns out that the performance of RVEA on WFG4, which has a relatively simple search landscape, is generally insensitive to the settings of f_r , as shown in Fig. 5(b). By contrast, on DTLZ3, which has a difficult multimodal search landscape, a too small f_r , i.e., employing the reference vector adaptation too frequently, will lead to a significant deterioration of the performance of RVEA, as indicated by Fig. 4(a). Based on such observations, it can be concluded the performance of RVEA is insensitive to the settings f_r on problems with simple landscapes, and a large value of f_r , i.e., a low frequency of employing the reference vector adaptation, is helpful in maintaining stability

on problems with complex search landscapes.

IV. THE SCALARIZATION FUNCTIONS OF WEIGHTED TCHEBYCHEFF AND PBI

A. Weighted Tchebycheff

The scalarization function of the weighted Tchebycheff approach can be presented as:

$$\text{minimize } g^{tch}(\mathbf{x}|\mathbf{w}, \mathbf{z}^{min}) = \max_{i=1}^M \{w_i |f_i(\mathbf{w}) - z_i^{min}|\}, \quad (1)$$

where $\mathbf{w} = (w_1, w_2, \dots, w_M)$ is a weight vector and $\mathbf{z} = (z_1^{min}, z_2^{min}, \dots, z_M^{min})$ is the ideal point.

B. PBI

The scalarization function of the penalty-based boundary intersection (PBI) approach can be presented as:

$$\text{minimize } g^{pbi}(\mathbf{x}|\mathbf{w}, \mathbf{z}^{min}) = d_1 + \theta d_2, \quad (2)$$

with

$$d_1 = \frac{\|(\mathbf{F}(\mathbf{x}) - \mathbf{z}^{min})^\top \mathbf{w}\|}{\|\mathbf{w}\|}, \quad (3)$$

and

$$d_2 = \|\mathbf{F}(\mathbf{x}) - (\mathbf{z}^{min} + d_1 \frac{\mathbf{w}}{\|\mathbf{w}\|})\|, \quad (4)$$

where $\mathbf{w} = (w_1, w_2, \dots, w_M)$ is a weight vector, $\mathbf{z} = (z_1^{min}, z_2^{min}, \dots, z_M^{min})$ is the ideal point, and θ is a user-specified parameter that balances between d_1 and d_2 .

V. THE CONSTRAINTS IN C1-DTLZ1, C2-DTLZ2 AND C3-DTLZ4

A. C1-DTLZ1

C1-DTLZ1 is known as a *Type-1* constrained problem, where the feasible space is restricted to a small subregion of the objective space, though the PF is not changed:

$$c(\mathbf{x}) = 1 - \frac{f_M(\mathbf{x})}{0.6} - \sum_{i=1}^{M-1} \frac{f_i(\mathbf{x})}{0.5} \geq 0, \quad (5)$$

B. C2-DTLZ2

C2-DTLZ2 is known as a *Type-2* constrained problem, where the feasible regions are restricted to $M + 1$ hyperspheres of radius r :

$$c(\mathbf{x}) = -\min_{i \in \{1, \dots, M\}} \left[(f_i(\mathbf{x}) - 1)^2 + \sum_{j=1, j \neq i}^M f_j^2(\mathbf{x}) - r^2, \left[\sum_{i=1}^M \left(f_i(\mathbf{x}) - \frac{1}{\sqrt{M}} \right)^2 - r^2 \right] \right] \geq 0 \quad (6)$$

where $r = 0.4$ for $M = 3$ and $r = 0.4$ otherwise.

C. C3-DTLZ4

C3-DTLZ4 is known as a *Type-3* constrained problem, where the original PF is no more optimal due to multiple constraints:

$$c_i(\mathbf{x}) = \frac{4}{f_i^2(\mathbf{x})} + \sum_{j=1, j \neq i}^M f_j^2(\mathbf{x}) - 1 \geq 0, \quad (7)$$

where $i = 1, \dots, M$.
